Commitment

ABSTRACT

It is widely accepted that one of the most important characteristics of an effective pollution control policy is to provide firms with credible incentives to make long-run investments in R&D that can drastically reduce pollution. Recognizing that a government may be tempted to revise its policy design after innovations become available, this note shows how the performance of two policy instruments—prices (uniform taxes) and quantities (tradeable pollution permits)—differ in such a setting. I also discuss the gains from combining either instrument with subsidies to adopting firms.

1. Introduction

It is widely accepted that one of the most important characteristics of an effective pollution control policy is to provide firms and individuals with credible incentives to make the long-run investments in R&D and capital equipment that will be needed to reduce pollution; see, for example, the articles in [Aldy and Stavins \(2007\)](#) in the context of climate change. A policy will be unable to induce such investments unless it is clear that the policy is likely to be enforced and is unlikely to be loosened up or repealed in the future. Then, central to the analysis of policy choice and design is the extent to which governments can credibly commit to a policy that can adequately compensate innovators for their investments ([Hoel, 2010](#)).¹ In this note I focus on the case of no commitment, i.e., the case in which governments revise their policy designs (not choices) if it is socially optimal to do so.²

There is a vast literature studying how different environmental policies provide firms with incentives to develop and adopt cleaner technologies (e.g., [Popp et al., 2009](#); [Requate, 2005](#)). Following practical experience ([Stavins, 2003](#)), most studies look at the performance of relatively simple policy instruments aimed at polluting sources such as standards, linear taxes and tradeable permits. It is also generally assumed that R&D is carried out by the

same polluting firms in an effort to reduce their abatement costs (e.g., [Montero, 2002](#)). If this is so and polluting firms are small (i.e., non-strategic), a completely informed regulator can implement the first-best amount of R&D and pollution by either using prices (i.e., linear tax) or quantities (i.e., tradeable permits).³

In this paper I focus on the case more relevant to many environmental problems, which is that innovations are developed by parties other than polluting firms ([Requate, 2005](#)). For simplicity I assume there is a single innovator who licenses its innovation to polluting sources facing an environmental policy that take the form of either prices or quantities; later I also allow the regulator to combine prices and quantities *a la Roberts and Spence (1976)*.

The paper closest to mine is [Laffont and Tirole \(1996b\)](#) who consider a single innovator that with some probability—increasing in the amount of R&D—can invent a pollution-free technology.⁴ Polluting firms can either buy permits, adopt the pollution-free technology (when is available) or shut down production. The authors argue that stand-alone spot markets for pollution permits provide no R&D incentives at all because the regulator can expropriate the innovation ex-post by offering a competing “technology” (pollution permits) and putting an arbitrary downward pressure on the licensing price. They show then that the social optimum can be restored by issuing options to pollute instead of permits. I depart from such framework in several

¹ [Hepburn \(2006\)](#) also offers a good discussion on the importance of commitment and credibility for the choice between different policy instruments.

² In an recent paper looking at 127 manufacturing industries, [Carrión-Flores and Innes \(2010\)](#) document that environmental policy (i.e., tighter standards) do respond ex-post to environmental innovations.

³ See, for example, [Laffont and Tirole \(1996a\)](#). If there are spillovers the regulator is still indifferent between prices and quantities. Obviously, she is not if there are information asymmetries ([Weitzman, 1974](#)).

⁴ Building on [Laffont and Tirole \(1996b\)](#), [Denicolo \(1999\)](#) and [Scotchmer \(2011\)](#) also consider a single innovator but their focus is more on the commitment case. See also [Fischer et al. \(2003\)](#).

directions. First, I stick to simple instruments—taxes or (plain) permits—that eventually could be combined. Second, I model the invention as a more continuous process. This is important as we can distinguish between drastic innovations and modest innovations.

After setting up the model in Section 2, I then explain, in Section 3, that prices and quantities are not always equivalent in the absence of commitment, but it very much depends on the type of innovation. Suppose, for example, that the innovator has developed a pollution-free technology. It is socially optimal ex-post to widely diffuse the technology and to completely phase out pollution. In a tax regime this can be done by lowering the tax level, virtually to zero if there are no adoption costs, and forcing the innovator to license his technology at a price equal to or slightly below the tax level. This cannot be achieved with permits, so the innovator can retain a large part of his rents. Issuing more permits puts downward pressure on the licensing price but also lowers the price of existing permits (which remain in the market) making it impossible to simultaneously diffuse the pollution-free technology and phase out pollution. As the quality of the innovation falls (i.e., the new technology removes a smaller fraction of a firm's emissions), the trade-off between lowering the licensing price and allowing more pollution disappears because an adopting firm must still purchase some permits together with the new technology. Here, the regulator can implement the ex-post social optimum with either prices or quantities.

In Section 4 I consider the possibility of using a hybrid instrument, in particular, of combining taxes or permits with a subsidy to polluting firms that adopt the new technology. The use of subsidies together with taxes offers no gain because taxes are ex-post socially efficient. Conversely, the combination of permits and subsidies offers some complementarity. In fact, the government comes close to implement the first-best for the case of very clean technologies. Ex-post the government does not want to remove the subsidy (and increase the number of permits) because it is the vehicle that helps inducing the socially optimal diffusion of the new technology. When the new technology is of lower quality the government wants to (partially) expropriate the innovator ex-post by removing the subsidies and increasing the number of permits. So in the absence of commitment (and for low-quality innovations) we are back to pure permits which are not different from taxes.

Extension to uncertainty is in Section 5. Many of the results of the previous sections carry through. Section 5 concludes emphasizing the advantage of permits combined with subsidies over taxes. In the case of drastic innovations, the combination of permits and subsidies allow the regulator to implement the social optimum regardless of its ability to commit to future policies. In other words, the policy design is time consistent. Taxes, on the other hand, do not perform nearly as well precisely because they work too well ex-post.

2. The model

2.1. Notation

There are two periods, $t = 1, 2$, and a continuum of polluting firms of mass one. For notational simplicity I abstract from discounting and first-period pollution. In the absence of regulation each firm produces a unit of output for a perfectly competitive output market and emits one unit of pollution. A firm's valuation for polluting one unit is $\theta \in [0, 1]$, that is, θ is the profit obtained by the firm when producing and polluting one unit. Alternatively, θ can be viewed as the firm's cost of abating pollution. Valuations are distributed according to the cumulative distribution $F(\theta)$, with density $f(\theta)$. I make the usual assumption that $(1 - F)/f$ is non-increasing in order to ensure concavity of the social welfare function. In some places I will also use that the demand for pollution is not too convex, that is, $f(p) + p f'(p) > 0$.⁵ The government

may not observe an agent's individual valuation θ but knows the distribution F and observes who pollutes and by how much.

I model the development of new technologies in a relatively simple way. Among other things, I abstract from competition among potential innovators. Thus, I consider one potential innovator, who at private cost $I(x)$ incurred at date 1 can develop the technology $x \in [0, 1]$ that removes a fraction x of a firm's emissions and where $I(0) = 0$, $I'(x) > 0$ and $I''(x) > 0$. In Section 6, I replace this deterministic R&D process by an stochastic one where at cost I the innovator develops technology x or inferior with probability $G(x|I)$. Higher investment I makes the development of a cleaner technology (i.e., higher x) more likely in the sense of first-order stochastic dominance: $\partial G(x|I)/\partial I \leq 0$. Both functions $I(x)$ and $G(x|I)$ are also known by the government. The technology x becomes available at the beginning of date 2. Polluting firms may incur an arbitrarily small but positive cost ε to install the new technology after paying a license fee r , net of adoption cost, to the innovator (for most part of the analysis we can set the adoption cost ε to zero). I am also assuming that the innovator's invention cannot be imitated, either because it is not feasible or because it is protected by a patent.⁶

The social damage of an additional unit of pollution is constant and equal to $h < 1$, so even in the absence of innovation it is socially optimal to have some pollution. To rule out uninteresting cases, I further assume that h is not too large; more specifically, $h < (1 - F(h))/f(h)$. This implies that an innovator with a pollution-free technology (i.e., $x = 1$) would, if unconstrained, price above h .⁷

The government's objective is to regulate pollution but also to provide the innovator with incentives to develop cleaner technologies.⁸ I restrict attention to policy instruments aimed at polluting firms; hence, I rule out that the government can sign an ex-ante contract (or negotiate ex-post) with the innovator.⁹ More specifically, the government has two instruments at hand to regulate pollution in period 2: either a pollution tax p per unit of pollution or an allocation of q tradeable pollution permits. Permits are allocated for free or auctioned off to a perfectly competitive permits market. In Section 5, I allow these instruments to be combined with a subsidy s to firms adopting the new technology. Note that unless $x = 1$, adopting firms still need to either buy permits or pay taxes to cover their $1 - x$ remaining emissions in period 2.

The government's potential commitment problem is captured by the fact that in period 2, and after the innovation has become available, the government can revise its period-1 policy design by either lowering the tax or issuing additional permits (in principle, it can also revise the policy upwards by either increasing the tax or buying back some permits). If the government decides to revise its policy design in period 2, I will assume that it does so before the innovator licenses his technology to firms.¹⁰

⁵ Again, relaxing this last assumption would introduce new elements to the model without altering the central message of the paper.

⁷ Since the new clean technology can be seen as a durable good (unless rented), we are implicitly assuming that the innovator is not fatally affected by the Coase conjecture. There are different ways in which this can happen, e.g., presence of arbitrarily small capacity costs (McAfee and Wiseman, 2008).

⁸ Scotchmer (2011) devotes large part of the paper to explain and discuss this "two-objective and one-instrument" problem.

⁹ As shown by Laffont and Tirole (1996b) the under-investment problem is readily solved if the government can sign an ex-ante contract with the innovator. Such contracts are rarely seen in practice, however, much less for clean technologies. Furthermore, those contracts are not free of commitment problems either; the current administration may refuse to respect a contract signed by the previous administration. Things become even more complicated if the regulator cannot observe investment.

¹⁰ As discussed in more detail below, assuming a different timing (i.e., simultaneous move between the regulator and the innovator in period 2) can change matters.

⁵ The aggregate demand for pollution is $D(p) = 1 - F(p)$, where p is the pollution price.

2.2. First-best

The government's first-best solution is given by the technology x and pollution level q (or pollution price p) that maximize the welfare function¹¹

$$W = -hq + \int_p^1 \theta f(\theta) d\theta - I(x) \quad (1)$$

Since adoption is virtually costless, it is socially optimal to have each operating firm installing x ; hence, there is an immediate connection between p and q

$$q = \int_p^1 (1-x)f(\theta) d\theta = (1-x)[1-F(p)] \quad (2)$$

Using Eq. (2), the first-order conditions for p and x are, respectively

$$h(1-x) - p = 0 \quad (3)$$

$$h[1-F(p)] - I'(x) = 0 \quad (4)$$

Denote by x^* and p^* the first-best technology and price levels that solve Eqs. (3) and (4). Condition (3) says that the benefit from the last unit of output, p^* , is equal to the pollution damage associated to it: h times the remaining emissions $1-x^*$. On the other hand, since $1-F(p^*)$ is industry output, condition (4) says that the additional cost of developing a technology marginally cleaner than x^* is exactly equal to the marginal benefit of having a cleaner industry.

3. Policies in the absence of commitment

Suppose the innovator has made available at period-2 technology x . After observing x and before the innovator licenses his technology to firms, the government is ready to revise its policy. I first analyze prices, which are easier, and then quantities.

3.1. Prices

Let p be the tax set by the government in period 2. Given technology x , the innovator's best response is to license his technology at price

$$r = \min\{px, r^m(x, p)\}$$

where $r^m(x, p)$ is the "unconstrained" monopoly price, which, assuming efficient rationing, is equal to

$$r^m(x, p) = \arg \max_r \pi = [1-F(r+p(1-x))]r$$

The monopoly price, however, is ruled out by assumptions (i) $(1-F(h))/f(h) > h$, and (ii) $[1-F(\theta)]/f(\theta)$ is non-increasing.¹² Hence, the innovator's best response is to price at (or slightly below) px and sell to all active firms (i.e., $\theta \geq p$). This results in pollution

$$q(p, x) = (1-x)[1-F(p)] \quad (5)$$

Anticipating the inventor's price response and Eq. (5), the government's chooses the tax p that solves

$$\max_p -hq(p, x) + \int_p^1 \theta f(\theta) d\theta$$

which leads to the first-order condition (3). It is not surprising that the tax instrument implements the ex-post social optimum since it

can exert as much downward pressure on the license price as needed.¹³ The innovator is forced to widely diffuse his technology (i.e., no rationing) at a price set by the government.

For the same reason the tax instrument works so well ex-post, it works poorly ex-ante, i.e., it leaves insufficient rents with the innovator (and zero rents in case he develops the cleanest technology). Consequently, the innovator underinvests relative to the first-best, i.e., $I(x_p^{nc}) < I(x^*)$, where x_p^{nc} denotes the technology developed under a price regime absent of commitment and is equal to

$$x_p^{nc} = \arg \max_x \{p(x)x[1-F(p(x))] - I(x)\} \quad (6)$$

where $p(x) = h(1-x)$. It is not difficult to show that $x_p^{nc} < x^*$.¹⁴

The underinvestment is such that the innovator will never develop anything cleaner than

$$\bar{x} = \frac{1}{2 - \bar{p}f(\bar{p}) / (1-F(\bar{p}))} < 1$$

(where $\bar{p} = h(1-\bar{x})$) even if R&D is costless. The underinvestment occurs because the government cannot credibly commit not to expropriate the innovator's rents ex-post (a patent protects the inventor from potential imitators but not from the government).

3.2. Quantities

Let q be the number of tradeable pollution permits issued by the government in period 2. To find the government's best (quantity) response to an available technology x , it is useful to start by finding the ex-post social optimum because, unlike with prices, it is not obvious that the regulator can always implement it with quantities. From Eqs. (2) and (3), the socially optimal allocation of permits is (recall that all operating firms install the new technology)

$$q^*(x) = (1-F(h(1-x)))(1-x) \quad (7)$$

This function is plotted in Fig. 1.¹⁵ In the absence of innovation it is optimal to allocate $q^*(x=0) = 1-F(h)$ permits, but if a pollution-free technology is developed it is optimal to completely phase out pollution, i.e., $q^*(x=1) = 0$.

Consider now the optimal response of an innovator with technology x and after q permits have been issued by the government. When q is sufficiently large, the innovator will find it optimal to ration the supply of the technology, that is, to set a license fee such that only a fraction of active firms adopt the new technology. More specifically, the innovator solves

$$\max_y \pi(y) = yp(x, q, y)x \quad (8)$$

where y is the number of licenses sold in equilibrium, $p(x, q, y)$ is the equilibrium price of permits and $r = xp(\cdot)$ is the license fee charged by the innovator. The equilibrium price of permits $p(x, q, y)$ is found from the market clearing condition in the permits market that is

$$1-F(p) = q + yx \quad (9)$$

¹³ Note that if $x=1$ the government will set p slightly above zero, providing the innovator with enough room to undercut the government's price.

¹⁴ Take the first-order condition that solves for x_p^{nc} , which is $h(1-F(p)) - hx[2(1-F(p)) - p'f(p)] - I'(x) = 0$, and then notice, from the assumptions above, that the term in square brackets is strictly positive.

¹⁵ Note that $\partial q^*(x)/\partial x = -[1-F(h(1-x))] + h(1-x)f(h(1-x)) < 0$.

¹¹ I abstract from the social cost of public funds because it would not change the results of the paper other than making subsidies costlier to implement.

¹² With these assumptions $\partial \pi / \partial r|_{r=p} = 1-F(p) - f(p)p > 0$ for all $p \in [0, h]$.

Fig. 1. Regulator and innovator's ex-post responses.

Solving (8), we find that in this "rationing" equilibrium the innovator will sell licenses.

$$y^m = \frac{p(\cdot)f(p(\cdot))}{x} < 1 - F(p) \quad (10)$$

Depending on x and q , there will be a point where the innovator just rations his supply of the clean technology, i.e., where $y^m = 1 - F(p) = q/(1-x)$. Using Eqs. (9) and (10), the combinations of q and x that just induce "rationing" are given by

$$F^{-1}\left(1 - \frac{q}{1-x}\right) f(F^{-1}(\cdot)) = \frac{qx}{1-x} \quad (11)$$

Denote by $q^r(x)$ the solution of Eq. (11), which is also plotted in Fig. 1 along with function $q^*(x)$ (I will shortly come back to the observation that $q^r(x)$ necessarily crosses $q^*(x)$ at some interior value of x).¹⁶

Thus, for any combination of q and x to the left of curve $q^r(x)$ in Fig. 1 the innovator is "capacity constrained" in that he sells his technology to all active firms in equilibrium, i.e., $y = q/(1-x) = 1 - F(p(\cdot))$. In this region, pollution permits and the clean technology work as perfect complements. Conversely, for any combination of q and x to the right of $q^r(x)$, the innovator rations supply, i.e., $y < q/(1-x) = 1 - F(p(\cdot))$. Here permits are a perfect substitute for the new technology, so the innovator optimizes along the residual demand $1 - F(p) - q$ and the price of permits becomes independent of x and given by (from Eqs. (9) and (10))

$$p = \frac{1 - F(p) - q}{f(p)} \quad (12)$$

It remains to determine the government's best response for any given x and anticipating the innovator's pricing reaction function. To facilitate the discussion, let $\hat{x}$ be the technology level where $q^*(x)$ and $q^r(x)$ cross (see Fig. 1), i.e.,

$$\hat{x} = \frac{\hat{p}f(\hat{p})}{1 - F(\hat{p})} \quad (13)$$

where $\hat{p} = h(1 - \hat{x})$. Furthermore, we will say that a technological development is drastic when $x > \hat{x}$ and modest when $x \leq \hat{x}$.¹⁷ Note that I am using the terms drastic and modest in a loose way; for example, if

¹⁶ Note that if $F(\theta)$ is the uniform distribution then $q^r(x) = (1-x)/(1+x)$.

¹⁷ The threshold $\hat{x}$ that separates drastic from modest innovations should go up as we add more innovators in the market that imperfectly compete for polluting firms.

$F(\theta)$ is uniform and $h = 1/3$ then $\hat{x} = 0.3$, which is not particularly clean. More importantly for our analysis, when the innovation is modest the government has no problems in implementing the ex-post social optimum: it will issue $q = q^*(x)$ permits, resulting in the first-best equilibrium price $h(1-x)$.

The government's response is a bit more involved when the innovation is drastic. The government cannot longer implement the ex-post social optimum because the latter falls in the innovator's rationing zone. So in principle, the government picks a number of permits independent of x as follows

$$q^0 = \arg \max_q \left\{ -hq + \int_{p(q)}^1 \theta f(\theta) d\theta \right\}$$

where $p(q)$ is implicitly given by Eq. (12). As shown in Fig. 1, q^0 is always strictly smaller than $\hat{q} \equiv q^*(\hat{x})$ and in many cases it is equal to zero¹⁸; for example, if F corresponds to the uniform distribution and $h \geq 1/4$. However, since the government would like to come as close as possible to the (ex-post) first-best, it can do better and pick $q^r(x)$ instead of q^0 for those cases in which $q^r(x) > q^0$. Thus, the government's best response is to issue $q = q^r(x)$ when $x \in [\hat{x}, x^0]$ and $q = q^0$ when $x \in [x^0, 1]$. In what follows I neglect this latter case by assuming that $q^0 = 0$ (and hence $x^0 = 1$) (we are basically saying that h is not too small; assuming otherwise would introduce more notation without adding much new to the problem).¹⁹

We can summarize this discussion in the following proposition.

Proposition 1. Prices and quantities are ex-post equivalent for "modest" innovations (i.e., when $x \leq \hat{x}$). When innovations are "drastic" (i.e., $x > \hat{x}$) quantities lead to less diffusion of the clean technology, less output, less pollution and more rents to the innovator.

The proof basically consists in showing that Fig. 1 is qualitatively correct; more specifically, that $q^r(x)$ crosses $q^*(x)$ from above at some $0 < \hat{x} < 1$. To gain intuition on the proposition it helps start with the case in which the innovator has developed a pollution-free technology, i.e., $x = 1$. It is ex-post socially optimal to diffuse the technology to all firms and to completely phase out pollution. In a tax regime this can be done by lowering the tax level to virtually zero (or slightly above the adoption cost ε if positive) forcing the innovator to license his technology at such price. All firms adopt the new technology and pollution is completely phased out. It is clear that this same outcome cannot be achieved with quantities. One way to force the innovator to license his technology to all firms for "free" is by issuing $q \geq 1$ (i.e., a total amount of permits equal or above the total amount of pollution in the absence of regulation). If the adoption cost is exactly equal to zero ($\varepsilon = 0$), one possible equilibrium in such a scenario—after the government has issued $q \geq 1$ permits and the innovator has priced his technology at $r = 0$ —is that all firms adopt the new technology and the totality of permits remain unused (this is the equilibrium adopted by Laffont and Tirole (1996b) in their Proposition 1 and where $\varepsilon = 0$). But another equally plausible equilibrium is that no firm adopts the new technology but instead all firms cover their emissions with (free) permits. Either equilibrium is equally good from the perspective of the polluting firms but not from the government's perspective. Obviously, there is also a continuum of equilibria with partial adoption.

This multiplicity is eliminated here, however, because $\varepsilon > 0$, no matter how small.²⁰ Therefore, if the government issues $q \geq 1$,²¹ permit

¹⁸ In fact $q^0 < \hat{q} \Leftrightarrow [1 - F(\hat{p})][f(\hat{p}) + \hat{p}f'(\hat{p})] + \hat{p}f^2(\hat{p}) > 0$, which holds for any demand function that is not too convex.

¹⁹ Note that $q^0 > 0$ implies that the government is willing to issue pollution above the ex-post social optimum for a sufficiently clean technology (i.e., $x > x^0$). This is so because the increase in industry output more than offsets the reduction in the diffusion of the new technology.

²⁰ Timing is also a powerful refinement even when $\varepsilon = 0$. Since permits are allocated before the technology is licensed to firms, why would any firm bother adopting the new technology if it has already enough permits to cover its emissions?

²¹ Note that according to this logic the government would also need to issue $q \geq 1$ if $x < 1$.

prices would collapse to zero and there would be nothing the innovator could do to outcompete the permits at non-negative profits. Furthermore, if the government issue $q < 1$ (but close to the unity) with the idea to generate a small but positive permit price, the innovator would not sell to the entire industry (if he does, the permit price would collapse to zero), but to a fraction of the residual demand $1 - q - F(p)$ at price (12). Therefore, the idea that the government can replicate with quantities what can be done with prices is simply not possible (unless one believes in an equilibrium where the totality of permits issued remain unused).²² Then, if a pollution-free technology becomes available, the best the government can do is issue no permits (because $q^0 = 0$) and let the innovator price his technology at the monopoly price.

Unlike taxes, quantities are too costly an instrument with which to exercise downward pressure on the license price for a pollution-free technology—or for any technology $x \in \mathcal{X}$ for that matter—because the adoption of the technology does not remove the permits issued by the government. This provides the innovator with a credible protection against ex-post expropriation by the government. It is then immediate that

Proposition 2. In the absence of commitment quantities provide more incentives for the development of "drastic" technologies than do prices (and equal for "modest" technologies).

In some cases, when h is relatively low, incentives for the development of drastic technologies can be even beyond first-best levels, leading to $x_q^{nc} > x^*$.²³

Propositions 1 and 2 present a clear trade-off between prices and quantities that prevents an unambiguous welfare ranking in the absence of commitment: prices provide less innovation incentives for the development of drastic technologies but are always ex-post (i.e., static) efficient unlike quantities.

3.3. Timing

We have assumed that the government enjoys a minimum commitment power that allows it to move first in period 2. This seems a reasonable assumption since policies are rarely changed so frequently; much less frequently than prices set by a private party. Yet, it is informative to ask what happens when government and innovator move simultaneously in the second period. In the quantity game context, such a simultaneous move would correspond to assuming that the government buys back the permits it issued after the innovator has licensed his technology to firms.

A change in the timing of moves has little or no effect in the quantity game,²⁴ but it can result in important changes in the price game. It turns out that prices look very much like quantities now. Take for example $x = 1$. If the innovator prices his technology at the monopoly price $1/f(0)$, the government's best response is to set the tax slightly above (for the same reason that $q^0 = 0$) so that all active firms adopt the clean technology.

4. A hybrid instrument

So far we have assumed that the government must restraint itself to a single instrument, either prices or quantities. The first in proposing to combine prices and quantities were Roberts and Spence (1976) in the context of asymmetric information. Here, however, the combination of

taxes and permits provides no gain. Maintaining the assumption that the government can only target polluting sources, in this section I explore the welfare gain from adding a third instrument—a subsidy to polluting sources adopting the new technology—to be combined with either the tax or the permits.²⁵

Let s be the subsidy per unit of reduction paid to an adopting firm; thus, a polluting firm adopting technology x gets a total subsidy of sx . In this hybrid design the innovator will license his technology at a price

$$r = px + sx = (p + s)x$$

where p can be either the tax or the equilibrium price of permits.

4.1. Prices and subsidies

It is immediately evident that there is no gain for prices in the absence of commitment since the tax policy is already ex-post efficient. Obviously, if the government can commit, it can implement the first-best by setting

$$p = h(1 - x^*) \text{ and } s = hx^*$$

Note that this is commitment to the actual values of the tax and subsidy not to rules that depend on x . The tax p ensures ex-post efficiency for technology level x^* and the subsidy s is the mark-up the innovator needs to develop the x^* technology.

4.2. Quantities and subsidies

The government combines q permits with a subsidy s . To fix ideas, consider first the case in which the government can commit to its policy design q and s .

Proposition 3. A government that can commit implements the first-best p^* and x^* with the following policy design

$$q^h = q^* = [1 - F(p^*)](1 - x^*)$$

$$s^h = \frac{1 - F(p^*)}{f(p^*)} x^*$$

Proof. All we need to show is that the above policy design induces the innovator to develop technology x^* . As with pure quantities, the innovator will never operate in the "rationing zone", so the equilibrium prices of permits $p(q, x)$ is given by

$$1 - F(p(q, x)) = \frac{q}{1 - x} \quad (14)$$

The innovator sells his technology x for $p(q, x)x + sx$, then his (ex-ante) problem is

$$\max_x \pi(x; q, s) - I(x)$$

where $\pi(x; q, s) = [p(q, x) + s]x[1 - F(p(q, x))]$. Replacing s^h and $\partial p(\cdot)/\partial x = -(1 - F)/(1 - x)f < 0$, as obtained from Eq. (14), into the innovator's first-order condition for R&D leads to the first-order condition (4).

²⁵ Subsidies to polluting sources are not that uncommon (e.g., tax credits for households installing solar panels, bonuses for drivers buying more fuel-efficient cars, etc.) unlike direct subsidies to R&D investments.

²² One way to remove the excess permits in the market would be for the government to buy back the permits issued after the innovator has licensed his technology to firms. This would surely change the timing of the game (provided the innovator can anticipate the permit buy-back) but not necessarily the results as we discuss below.

²³ For example, if F is uniform, $h = 1/4$ and $I(x) = cx/(1 - x)$ with $c = 0.01$, we have that $x^* = 0.79$ and $x_q^{nc} = 0.81$.

²⁴ For example, if $x = 1$, the government's best response to the innovator's monopoly pricing could still be $q = 0$.

While quantities are aimed for static efficiency (for any given technology level x), the subsidy plays the dual role of providing innovation rents and diffusion incentives. For instance, if R&D is costless, the innovator will anyway develop the pollution-free technology but it is the subsidy $s = 1/f(0)$ that achieves the full diffusion of the technology. Conversely, if R&D costs call for more modest technologies (i.e., $x^* < \hat{x}$), the subsidy plays no diffusion role (because the innovator is in the "capacity constrained" zone) but it does stimulate the innovator to develop a cleaner (first-best) technology. Because of this dual role it is not surprising that subsidies are costlier (i.e., larger) under quantities than prices whenever $x^* > \hat{x}$.²⁶

It is interesting to contrast this hybrid design with the first-best "permit and option" approach proposed by Laffont and Tirole (1996b), who only allow for pollution-free developments (the probability of developing the pollution-free technology is increasing in the amount of R&D).²⁷ In their mechanism, the government sells at date 1 securities to polluting firms at some price v . The holder of such security is offered the following choice for date 2, which the government commits to: either she exercises an option to purchase a pollution permit at price $p_0 - \Delta$ (where p_0 is the first-best price in the absence of innovation, which in our model is h) or she redeems the security to the government and receives Δ for it. As the probability of developing the free-pollution technology goes to one, v becomes a subsidy equal to the size of the welfare gain from the innovation.²⁸ In that sense there is a close connection with the hybrid mechanism presented here.

The hybrid policy raises other questions. One is about the government's budget. Even if pollution permits are auctioned off, the collected revenues are not enough to cover for the subsidy expenditures for very clean technologies (note that if $x^* = \hat{x}$, then $p^* = s^h$). Another question is the time consistency of the hybrid instrument and more generally the form of the hybrid policy in the absence of commitment. Since the hybrid policy is ex-post socially optimal, in principle the government would not be tempted to change it ex-post as long as subsidies constitute lump sum transfers. But if there is an arbitrarily small but positive cost of public funds, the government would like to reduce the subsidy ex-post: it would fully remove it for $x \leq \hat{x}$ and bring it down to the level that just induces full diffusion for $x > \hat{x}$.²⁹ Anticipating this commitment problem, the innovator will not invest as much in R&D. The good news is that for pollution-free technologies (or nearly so) the government does not (or barely does) adjust the subsidy; retaining the R&D incentives at the top.

4.3. Imperfect monitoring

Subsidies are sometimes criticized in that they may fail to reach the right individuals. Here the "right individuals" would be those polluting firms that are reducing pollution from the adoption of the new technology and not from other reasons. Suppose then, the government cannot exactly tell whether a firm's pollution reduction was the result of the adoption of the new technology—in which case the firm is entitled to the subsidy—or a cease in operations (or internal abatement at cost θ using conventional technologies). Let φ be the probability that the government can tell whether a firm is legitimately entitled to receive the subsidy or not.

For any given subsidy (per unit of reduction) s and allocation q announced at date 1, let p be the equilibrium price of permits. If so, firms with valuation $\theta \geq p + (1 - \varphi)s$ are the ones adopting the new

technology and firms with valuation $\theta < p + (1 - \varphi)s$ are the ones shutting down operations but still claiming the subsidy (since there is no penalty fee for dishonest behavior). Only a fraction $1 - \varphi$ of these latter firms end up receiving the subsidy.

The government's problem is now to choose q and s so as to solve

$$\max_{q,s} \left\{ -hq + \int_{p+(1-\varphi)s}^1 \theta f(\theta) d\theta - I(x(q,s)) \right\}$$

where p is the equilibrium price of permits and given by (the innovator has not abandoned the "capacity constrained" zone)

$$p(q, x, s, \varphi) = F^{-1}(1 - q / (1 - x)) - (1 - \varphi)s$$

When φ is not too low, the government can still implement the first-best; it allocates q^* permits and increases the subsidy to account for the imperfect monitoring, that is

$$s_m^h = \frac{1 - F(p^*)}{\varphi f(p^*)} x^*$$

The solution is efficient since $p + (1 - \varphi)s = h(1 - x^*)$. Furthermore, for this solution to be valid, it must hold that $p \geq 0$ or

$$\frac{\varphi}{1 - \varphi} \geq \frac{1 - F(p^*)}{p^* f(p^*)} x^* \quad (15)$$

The larger the subsidy the higher the effort the government must undertake to prevent cheating. If Eq. (15) does not hold, the government adjusts both the subsidy s and q .

To the extent that φ is not too low, imperfect monitoring does not introduce distortions. That can change if imperfect information is modeled in such a way that low-valuation firms need to do some costly adjustment to hide behind higher-valuation ones; for example, all firms need to emit $1 - x$ to be considered for the subsidy. One possibility to deal with this distortion is to think of a mechanism where the regulator can allocate both permits and subsidies simultaneously. At the end the mechanism may resemble the VCG auction mechanism of Montero (2008).

5. Uncertain R&D

So far we have assumed that the R&D process is fully deterministic, which is not entirely realistic. Suppose now that at private cost I incurred at date 1 the innovator develops a technology x which distributes according to the cumulative distribution function $G(x|I)$, with density $g(x|I)$. I assume that higher investment I makes the development of a cleaner technology (i.e., higher x) more likely in the sense of first-order stochastic dominance: $\partial G(x|I) / \partial I \leq 0$. The government knows the function $G(x|I)$ but does not observe investment I ; thus, even if feasible, it cannot write a contract with the innovator on I . Uncertainty introduces new challenges to the government because the more uncertain the R&D process is the less likely the government wants to commit ex-ante to a rigid policy whether it is based on prices, quantities or a combination of quantities and subsidies.

5.1. First-best

The first best is given by the ex-post policy function $p^*(x) = h(1 - x)$ and the ex-ante investment

$$\begin{aligned} I^* &= \arg \max_I E \left[W(I|p^*(x)) \right] \\ &= \int_0^1 \left\{ -h \left[1 - F(p^*(x)) \right] (1 - x) + \int_{p^*(x)}^1 \theta f(\theta) d\theta \right\} g(x|I) dx - I \end{aligned}$$

²⁶ It is not difficult to show that $1 - F(p^*) > hf(p^*)$. We know, by assumption, that $1 - F(h) > hf(h)$ and that $(1 - F(p))/f(p)$ is non-increasing in p .

²⁷ They also consider a positive shadow cost of public funds.

²⁸ More precisely, to satisfy the individual rationality constraint we require $v \leq p_0(1 - z) - w$, where z is the probability of developing the pollution-free technology and w is the social value of such innovation. Note that in this formulation I am assuming that the social cost of public funds is zero.

²⁹ If the cost of public funds is not small, the government will reduce the subsidy even further for the case $x > \hat{x}$ at the expense of less diffusion and R&D investment.

Integrating by parts, we obtain that the socially optimal amount of investment solves

$$\int_0^1 -h[1-F(p^*(x))] \frac{\partial G(x|I)}{\partial I} dx - 1 = 0$$

which has the same interpretation as Eq. (4). The marginal cost of an additional unit of R&D is exactly equal to the expected marginal benefit of having a cleaner industry.

5.2. Prices vs quantities

The introduction of uncertainty does not change much of the trade-off in the choice between prices and quantities in the absence of commitment. When the government cannot commit, we know that the ex-post social optimum can be implemented with either prices or quantities to the extent that $x \leq \hat{x}$; if $x > \hat{x}$, the optimal quantity response is $q^r(x) < q^*(x)$. Because of the latter inefficiency, investment will be higher under quantities. In fact, the amount of investment I in any policy regime is given by

$$-\int_0^1 \pi'_k(x) \frac{\partial G(x|I)}{\partial I} dx - 1 = 0$$

where $\pi_k(x) = p(x)x[1 - F(p(x))]$ is the innovator's profit as a function of the technology developed under policy $k \in \{p, q\}$ and $p(x)$ is either the tax or the equilibrium price of permits. It is clear from the ex-post analysis of Section 3 that $\pi'_p(x) = \pi'_q(x)$ for $x \leq \hat{x}$ and $\pi'_p(x) < \pi'_q(x)$ for $x \geq \hat{x}$. Note that $\pi'_p(x)$ becomes negative for higher values of x ,³⁰ so eventually we can have the corner $I_p^{nc} = 0$. We can then establish

Proposition 4. $I_p^{nc} < I_q^{nc} < I^*$. Note that under deterministic R&D there may be cases in which the innovator invests in R&D beyond first-best levels. That never happens here because the innovator does not control the outcome of the innovation.

5.3. Hybrid instrument

As in the certainty case, we want to explore whether the combination of permits and subsidies can implement the first-best when R&D is stochastic. We want to find price and subsidy functions that both: are efficient ex-post and provide first-best investment incentives ex-ante. For the latter, we need the ex-post functions be such that

$$\pi'(x) = h[1 - F(h(1-x))]$$

for all x . One policy candidate is the ex-post efficient combination of permits and subsidies that generate the following rents for the innovator

$$\pi(x) = [p^*(x) + s(x)]x[1 - F(p^*(x))]$$

where $p^*(x) = h(1-x)$ and

$$s(x) = \max \left\{ \frac{1 - F(h(1-x))}{f(h(1-x))} x - h(1-x), 0 \right\}$$

Note that $s(x) = 0$ for $x \leq \hat{x}$ (i.e., for modest innovations). Unfortunately, this ex-post efficient policy rule can generate too large rents for the innovator, leading to excessive investment. It remains to be investigated what is the optimal (second-best)

mechanism that can be designed assuming that the policy instruments are exclusively aimed at polluting sources.

6. Conclusions

I conclude by emphasizing the advantage of quantities (i.e., permits) combined with subsidies over prices (i.e., taxes). In the case of drastic innovations (i.e., pollution-free innovations or nearly so), the combination of permits and subsidies allow the government to implement the social optimum regardless of its ability to commit to its original policy design. Taxes, on the other hand, do not perform nearly as well when governments cannot commit, simply because they work too well ex-post. Indeed, the ex-post social optimum can always be implemented with taxes regardless of whether the innovation is super clean or not. We cannot say the same for (pure) quantities that can only implement the ex-post social optimum when the new technology is not so clean that it needs to be bundled with permits. The fact that permits perform poorly ex-post for super clean technologies is what provides the government with commitment power not to "expropriate" the innovator ex-post and to keep the subsidies for diffusion purposes. In order to prevent the government from running a large deficit as a result of the subsidies, permits should be auctioned off.
